## **Abstract**

We document that stocks with the strongest prior 12-month returns experience a significant average market-adjusted return of 1.58 percent during the five trading days before their earnings announcements and a significant average market-adjusted return of -1.86 percent in the five trading days afterward. These returns remain significant even after accounting for transactions costs. We empirically test a limited attention explanation for these anomalous returns – that stocks with sharp run-ups tend to attract individual investors' attention, and investment dollars, particularly before their earnings announcements. Our analysis suggests that the trading decisions of individual investors are at least partly responsible for the return pattern we observe.

# Limited Attention and the Earnings Announcement Returns of Past Stock Market Winners

## *Introduction*

This paper examines whether past stock market winners exhibit a predictable return pattern around their earnings announcements. Our analysis is motivated by the prior work of Trueman et al. (2003) who document an economically large abnormal return over the five days prior to internet stocks' earnings releases during the 1998-2000 period, and a sharp reversal over the subsequent five days. Trueman et al.'s (2003) sample period coincides with a time when internet stocks were rising rapidly. This invites the question of whether the documented return pattern is unique to internet stocks during a relatively short time period, or whether it is a more general phenomenon which manifests itself in stocks with strong prior returns.

Our analysis finds the phenomenon to be widespread. For the thirty-five year period beginning in 1971, the top percentile of stocks in terms of past twelve-month price performance (sometimes referred to as the past winners) experience a significant average market-adjusted return of 1.58 percent during the five days prior to their earnings announcements (the "pre-announcement period") and a significant average market-adjusted return of -1.86 percent in the five days after (the "post-announcement period").<sup>1</sup> By way of contrast, the average pre-announcement market-adjusted return for our entire sample of stocks is a meager 0.30 percent, while the average post-announcement market-adjusted return is a negligible -0.1 percent.<sup>2</sup>

---

<sup>1</sup> In untabulated results, we find that only 30% of the past winners are high-tech stocks.

<sup>2</sup> These returns are similar in magnitude to those documented by Ball and Kothari (1991) and Berkman and Truong (2006). They find small average pre-announcement abnormal returns of 0.17 and 0.34 percent, respectively, and a negligible average abnormal return of -0.01 percent post-announcement. While not reporting abnormal returns, Chari et al. (1988) find an average pre-announcement *raw* return of 0.29% and an average post-announcement *raw* return of 0.26%.

To ensure that same-day earnings announcements are not biasing upward the significance of our results, we repeat our analysis, replacing the daily returns of firms announcing on the same date with a single observation whose daily returns are equal to the average of those concurrent individual announcements. Average market-adjusted returns remain significant and of similar magnitude: 1.5 percent during the pre-announcement period and -1.77 percent post-announcement.

To estimate the return that investors could have earned by exploiting these patterns during our sample period we form two equally-weighted, calendar-time portfolios. The first is comprised of those past winners whose earnings are to be announced within the next five trading days (the pre-announcement portfolio); the second is comprised of those past winners whose earnings had been announced within the last five trading days (the post-announcement portfolio).<sup>3</sup> We find a significant average daily four-factor abnormal return of 33 basis points for the pre-announcement portfolio and a significant -28 basis points for the post-announcement portfolio. Multiplying by five to put these numbers on a comparable footing with the five-day pre- and post-announcement returns yields average abnormal returns of 1.65 percent and -1.40 percent, respectively. These are of the same order of magnitude as our event-time returns.

There are two sources of noise in our estimates of pre-announcement and post-announcement period returns. The first is uncertainty over the exact timing of some of the announcements in our sample, which leads to uncertainty over the beginning and ending dates of our pre- and post-announcement periods. The second is the presence of intraday earnings announcements, which make it impossible to precisely separate pre-announcement and post-announcement returns (unless intraday pricing data is available). To abstract from these sources

---

<sup>3</sup> Full implementation of the pre-announcement strategy depends on investors knowing in advance firms' earnings announcement dates. See Section II.3.iii for a detailed discussion and analysis of this issue.

of noise we recalculate our pre- and post-announcement returns for just those earnings announcements whose dates can be verified through press releases and that occur outside of regular trading hours. The average pre-announcement period market-adjusted return for this subsample is 3.09 percent, which is almost double that of our top percentile as a whole.<sup>4</sup> The corresponding return for the post-announcement period, -3.05 percent, is over 60 percent larger in magnitude than that of our top percentile sample.<sup>5</sup>

These returns are gross of transactions costs, which stem principally from the bid-ask spread and brokerage commissions. To account for the impact of the bid-ask spread, we recompute returns under the assumption that all purchases are executed at the prevailing ask price while all sales are executed at the prevailing bid price. Doing so we find that, once again, average pre-announcement (post-announcement) market-adjusted returns are reliably positive (negative), both for our sample as a whole (with average market-adjusted returns of 0.94 percent during the pre-announcement period and -0.85 percent post-announcement) as well as for the subsample of announcements occurring outside of normal trading hours (1.66 percent pre-announcement and -1.34 percent post-announcement). Brokerage commissions lower these returns only slightly; the average pre-announcement (post-announcement) market-adjusted return, net of transactions costs, remains significantly greater (less) than zero.

We examine whether limited attention – the notion that individual investors are more likely to buy stocks that draw their attention – is a possible explanation for this anomalous return

---

<sup>4</sup> Like Trueman et al. (2003) we define the pre-announcement period for this subsample as extending through the market open after the earnings release.

<sup>5</sup> Our return pattern is distinct from that of the well-documented post-announcement drift (see, for example, Bernard and Thomas (1989) and Foster et al. (1984)). That phenomenon is evidenced by the continuation of post-announcement returns over a relatively long period of time, rather than a reversal of abnormally high pre-announcement returns in the immediate post-announcement period. On an annualized basis, the returns we document are much larger than those generated by the post-announcement drift.

pattern. Limited attention has been conjectured as an explanation for investors' underreaction to earnings surprises (Hirshleifer et al., 2008 and Hou et al., 2006), their underreaction to the information in pro-forma earnings announcements (Doyle et al., 2003), the price impact of Friday earnings releases (Della Vigna and Pollett, 2005), observed investor over-optimism with respect to firms with high levels of net operating assets (Hirshleifer et al., 2004), the average stock price increase around earnings announcements (Frazzini and Lamont, 2007), and the abnormally high levels of individual investor share purchases around the time of earnings announcements (Lee, 1992 and Barber and Odean, 2008).

The stocks we focus on likely attract investors' attention due to their sharp past returns.<sup>6</sup> Their attention is likely to be further heightened just prior to the firms' earnings announcements – another attention-grabbing event. Similar to Barber and Odean (2008), we test this possible explanation by calculating the abnormal order imbalance (as defined in Lee (1992)) for small, medium-sized, and large traders, around the time of our past winners' earnings announcements. Since smaller investors are arguably the less sophisticated ones, they are more likely to be motivated to buy stocks with strong prior returns just before the earnings release. Consequently, we would expect to observe an unusually large number of buyer-initiated trades relative to seller-initiated trades in the pre-announcement period for these traders, but not necessarily for larger ones. Once earnings are released and the focus shifts from these stocks, this positive abnormal order imbalance should disappear.

Our results are consistent with these conjectures. During the pre-announcement period small and medium-sized traders evidence a significantly positive abnormal order imbalance. In contrast, the imbalance is insignificant for large traders. In the post-announcement period the

---

<sup>6</sup> Consistent with this conjecture, Barber and Odean (2008) find a positive abnormal order imbalance for individual investors in stocks with large prior-day price movements.

positive abnormal order imbalances of the small and medium-sized traders disappear.<sup>7</sup> This evidence suggests that limited attention on the part of small, naïve investors is at least partly responsible for the observed return pattern around the earnings announcements of past stock market winners. A number of supplementary tests we perform all support this conclusion.

In contemporaneous work, Frazzini and Lamont (2007) also analyze the abnormal daily returns around firms' earnings announcements, albeit unconditional on prior stock price movements. They document a 9-day pre-announcement period (ending two days before the announcement date) average abnormal return of 0.25 percent and an additional 0.30 percent positive return premium during the 10 days afterward (beginning two days after the announcement). Over the three days surrounding the earnings announcement, the average abnormal return is 0.21 percent. The authors also find a positive average abnormal order imbalance for the large traders prior to the earnings announcement, which turns negative just afterward. For the small traders, the average abnormal order imbalance hovers around zero during the entire period, except for the three days surrounding the earnings announcement, when it is sizable. The authors posit that the pre-announcement price increase stems from buying by large traders, who are anticipating an increase in the buying of small traders around the earnings announcement and an accompanying increase in prices.

Our findings provide a number of insights for future research. First, they reveal the importance of controlling for prior stock returns when measuring the price reaction to earnings announcements. Second, they suggest that long-term price momentum strategies can be

---

<sup>7</sup> In contrast to our results, Barber and Odean (2008), Hirshleifer et al. (2008), and Lee (1992) find increased trading by small investors *after* the earnings announcement. They argue that the announced earnings capture small investors' attention and motivate them to trade, whether the earnings news is good or bad. These analyses do not condition on prior stock returns. In cases where there has been a sharp prior price increase, we argue that small investors' focus is drawn to earnings announcements *before* they occur and that they increase their trading at that time.

improved upon by deliberately avoiding the sale of stock during the week after earnings announcements.<sup>8</sup> Third, they open up the possibility that previously documented short-term return reversal results might be partly explained by the phenomenon documented here. If so, then excluding earnings announcement periods from the analysis has the potential to significantly reduce the returns to short-term momentum strategies.<sup>9</sup>

The plan of this paper is as follows. In Section I we describe our sample selection process and present descriptive statistics. In Section II we analyze the earnings announcement returns of stocks displaying strong prior performance. Potential explanations for the anomalous return pattern we observe are explored in Section III. A summary and conclusions section ends the paper.

## **I. Sample Selection and Descriptive Statistics**

Our sample consists of all quarterly earnings announcements on *COMPUSTAT* issued between January 1, 1971 and September 30, 2005 by firms (a) that are listed on *CRSP*, (b) that have a December 31 fiscal year-end, and (c) whose stock price at the end of the previous quarter is at least \$5. These requirements yield a sample of 293,630 firm-quarter observations.<sup>10</sup>

---

<sup>8</sup> Jegadeesh and Titman (1993), among others, show that a strategy of buying stocks that have performed well in the recent past and selling those that have performed poorly generates significant positive returns over three to twelve month holding periods.

<sup>9</sup> Lehmann (1990) conditions on prior one-week performance and finds that the best (worst) performing stocks underperform (outperform) the next week. Our work is distinctly different from his in that we are *not* conditioning on prior-week winners and are not focusing on *whether* return reversals exist around earnings announcements. Rather, we are analyzing the returns of past 52-week winners, both before and after their earnings announcements. We find strong positive market-adjusted returns in the pre-announcement period and sharp negative market-adjusted returns post-announcement. Note that given the differing natures of our analyses, it would be impossible to predict from his results that this pattern would exist. That the returns we document are much higher than his is further evidence of the differences between the two analyses. See also Jegadeesh (1990) and Gutierrez and Kelley (2008) for an analysis of short-term price reversals.

<sup>10</sup> We have excluded from our sample all announcements with *COMPUSTAT* issue dates more than 90 days after quarter end since those dates are almost certainly in error.

For all the firms in our sample with earnings announcements in quarter  $t$ , we compute raw stock returns for the 12-month period ending on the last trading day of quarter  $t-1$ .<sup>11</sup> We rank the stocks in ascending order according to their returns, and partition the firms into deciles. Table 1 presents descriptive statistics for each decile. As reported in panel A, average end-of-quarter market value increases monotonically from decile 1 (\$775 million) to decile 8 (\$2,267 million). This is not surprising since firms in higher deciles have experienced greater percentage share price increases (and greater percentage increases in market value) than those in lower deciles. Average market values decrease as we move to deciles 9 (\$1,941 million) and 10 (\$1,243 million). This drop is consistent with extreme returns being more prevalent in less established firms, which tend to be smaller in size. The median end-of-quarter market values display a similar pattern. They increase monotonically from decile 1 (\$130 million) to decile 7 (\$333 million) and then decrease to \$213 million for decile 10.

Panel B presents the average prior 12-month raw return for each decile; by construction, it is monotonically increasing across deciles. Not surprisingly, the average raw returns for the bottom and top deciles, containing the most extreme returns, are particularly large. The average raw return of -39.5 percent for the first decile is more than twice the size of that of the second decile, while the average raw return for the tenth decile, 153.5 percent, is 2½ times that of decile nine.

The average market-adjusted return during the pre-announcement period (the five trading days up to and including the earnings announcement date as recorded in *COMPUSTAT*) appears

---

<sup>11</sup> For a firm whose earnings announcement date falls within the first 5 trading days of quarter  $t$ , the prior 12-month return accumulation period ends the day before the pre-announcement period begins. This ensures that there is no overlap between the two periods.

in panel C for each decile.<sup>12</sup> The corresponding returns for the post-announcement period (the five trading days after the earnings announcement date) are presented in panel D. There is an almost monotonic increase in pre-announcement average market-adjusted returns as we move from lower to higher deciles. Moreover, the average market-adjusted return for the top decile, 0.83 percent, is more than 50 percent greater than that of the ninth decile and is almost three times as large as the average pre-announcement market-adjusted return of 0.3 percent over our entire sample.

The negative average post-announcement market-adjusted return of the first decile, -0.29 percent, is suggestive of price momentum, with the negative prior 12-month returns continuing into the post-announcement period. In contrast, the negative average market-adjusted return of the top decile, -0.71 percent, reflects a sharp reversal of the returns generated both in the pre-announcement period and over the prior 12 months. It is over seven times the size of the average post-announcement market-adjusted return of -0.1 percent for our sample as a whole.<sup>13</sup>

## **II. The Top Percentile**

### *II.1. Descriptive Statistics*

The results obtained thus far suggest the possibility that the return reversal pattern observed in the top decile is even sharper within the highest percentile. To investigate this possibility, we partition the top decile into ten percentiles according to prior 12-month return. Table 2 provides descriptive statistics for each of these percentiles. As seen from panel A, average market values exhibit a mostly decreasing trend as we move from the 91<sup>st</sup> percentile

---

<sup>12</sup> For the market return we take the value weighted return, including dividends, of all NYSE/AMEX/NASDAQ firms.

<sup>13</sup> As a robustness check, we rank stocks based on prior 3-month, 6-month, and 9-month returns. Untabulated results are both qualitatively and quantitatively similar to those reported here.

(\$1,872 million) to the 100<sup>th</sup> percentile (\$726 million). The same is true for median market values, which decrease from \$256 million for the 91<sup>st</sup> percentile to \$168 million for the top percentile. The prior 12-month return (panel B) varies over a wide range, from an average of 81.8 percent for the 91<sup>st</sup> percentile to 399.0 percent for the top percentile. That top percentile return is almost twice the size of the corresponding return for the 99<sup>th</sup> percentile and is over twice the average return for the top decile overall.

Panels C and D report average pre-announcement and post-announcement market-adjusted returns for the top 10 percentiles. These returns generally increase in magnitude as we move from the 91<sup>st</sup> to the 100<sup>th</sup> percentile. The average pre-announcement market-adjusted return for the top percentile, 1.36 percent, is over 60 percent higher than that of the top decile as a whole. The top percentile's average post-announcement market-adjusted return of -1.75 percent is over twice the size of that for the top decile. Given their economically large pre- and post-announcement returns, we focus the remainder of our analysis on this top percentile of observations.<sup>14</sup>

## *II.2. Refining the Earnings Announcement Dates*

There are two drawbacks to using the *COMPUSTAT* database to obtain earnings announcement dates. First, the dates provided are not always correct. Second, the times of the earnings releases aren't provided. To understand why the latter is an issue, consider two firms that release earnings on the same day, one before normal trading hours begin and one after they end. For the firm announcing before the market opens, the post-announcement period actually

---

<sup>14</sup> We repeat this analysis, broadening our sample to include firms with fiscal year-ends at the end of March, June, September, or December. This results in an increase in sample size of 890 observations (from 2,868 to 3,758). Untabulated results reveal a significant 1.49 percent (-1.84 percent) average pre-announcement (post-announcement) market-adjusted return.

begins with that trading day. For the firm announcing after the market closes, the post-announcement period begins on the next trading day.<sup>15</sup> Not knowing the time of the earnings release then leaves in doubt the exact end of the pre-announcement period and beginning of the post-announcement period.

To mitigate the impact these ambiguities have on our analysis, we turn to the actual earnings press releases, when available, to obtain the precise dates and times of the earnings announcements within our top percentile. (The *Factiva* database is our source of press releases.) If the time of a press release is either before the market opens or during normal trading hours, the previous trading day is set as the last day of the pre-announcement period.<sup>16</sup> If the time of the press release is after regular trading hours, the just-ended trading day is the end of the pre-announcement period. If the press release has no time stamp, then we arbitrarily assume that the announcement is made after trading hours and take as the last trading day of the pre-announcement period the day of the release. To the extent that these announcements are actually made before or during trading hours, this assumption has the effect of artificially dampening the positive pre-announcement period returns. This is because the actual first day of the post-announcement period (and its associated negative returns) will mistakenly be included within the pre-announcement period (and its positive returns). For an earnings announcement without an accompanying press release on *Factiva*, we end the pre-announcement period on the *COMPUSTAT* announcement date. For simplicity, and where it will not cause confusion, we sometimes refer to the last day of the pre-announcement period as the earnings announcement day.

---

<sup>15</sup> With after-hours trading more prevalent in recent years, the market response to these earnings releases often begins after regular trading hours on the earnings announcement day.

<sup>16</sup> If there are several press releases pertaining to the same earnings announcement in *Factiva*, we take the disclosure time to be that of the earliest release.

A by-product of our detailed examination of each observation in the top percentile is the identification of a number of observations which clearly have data errors. Dropping those observations leaves us with a final sample of 2,868 earnings announcements. Press releases with date and time stamps were found for 2,314, or 81 percent, of them. For 55 percent of those observations, the press release and *COMPUSTAT* announcement dates are identical; for 42 percent the *COMPUSTAT* date is between one and five days after that of the press release.

For our final sample, Table 3 presents the average daily and cumulative market-adjusted returns over the pre- and post-announcement periods.<sup>17</sup> Average daily pre-announcement returns are all positive, and are significant for days -2 through 0 (where day 0 denotes the last day of the pre-announcement period). Average daily post-announcement returns are all negative and significant. Cumulative market-adjusted returns over the pre- and post-announcement periods average 1.58 and -1.86 percent, respectively; both are reliably different from zero.

Figure 1 plots the year-by-year average pre- and post-announcement market-adjusted returns. Our results are generally consistent over time, with positive pre-announcement and negative post-announcement returns characterizing most of the individual years of our sample. Of the 35 years in our sample period, 28 have positive average market-adjusted pre-announcement returns, while 30 have negative average market-adjusted post-announcement returns. Given the high  $t$ -statistics for the pre-announcement and post-announcement period returns reported in Table 3, the consistency over time is not surprising.

---

<sup>17</sup> In calculating the cumulative market-adjusted return for the pre-announcement period we drop observations with one or more missing daily returns. We do the same for the post-announcement period. This leaves us with 2,866 observations pre-announcement and 2,864 post-announcement.

Our full-period returns are also consistent across firm size. We use the Fama and French (2007) definitions of small and large stocks to partition our sample.<sup>18</sup> In untabulated results we find that small stocks exhibit a pre-announcement average market-adjusted return of 2.04 percent; the corresponding return for large stocks is 1.3 percent. For the post-announcement period the average market-adjusted return is -2.30 percent for small stocks and -1.63 percent for large ones. All of these returns are reliably different from zero. That the results are stronger for smaller stocks is not surprising, as there are arguably fewer sophisticated investors following those firms.

Returning to the full-sample results, we can view them in a broader context by expanding the pre-announcement period to the 20 trading days prior to, and including, day 0, and the post-announcement period to the 20 trading days afterward. In order to ensure that the prior return accumulation period does not overlap with the pre-announcement period, we end the accumulation of returns (for this analysis only) one month before quarter end. The composition of the top percentile is then determined using this shortened return accumulation period. Table 4 presents the average daily market-adjusted returns from day -19 through day 20, as well as the cumulative average market-adjusted returns (CAR). Figure 2 depicts the CAR graphically.<sup>19</sup> As the figure and table reveal, the CAR is almost monotonically increasing during the pre-announcement period, with the rate of increase growing in the few days before the earnings announcement. The mean of the average daily market-adjusted returns is 0.11 percent during the period from day -19 to day -5, jumping to an average of 0.35 percent during days -4 through 0.

---

<sup>18</sup> Fama and French (2007) define small stocks as those with market caps between the 20<sup>th</sup> and 50<sup>th</sup> percentiles of all NYSE stocks and large stocks as those with market caps above the 50<sup>th</sup> percentile. They characterize those stocks with market caps below the 20<sup>th</sup> percentile as microcaps. We do not separately report pre- and post-announcement returns for the microcaps since there are only 54 of them in our top percentile sample.

<sup>19</sup> Since the composition of the top percentile of stocks changes when the shorter prior return period is used, the average daily market-adjusted returns for days -4 through 5 differ somewhat from those reported in Table 3.

After the announcement the CAR abruptly turns down, decreasing most rapidly during the first few post-announcement days and continuing downward, almost without interruption, through the 13<sup>th</sup> post-announcement day. For days 1 through 5 the mean of the average daily market-adjusted returns is -0.35 percent, decreasing in magnitude to -0.06 percent over days 6 through 13. At that point it resumes its upward trend, averaging 0.12 percent daily for days 14 through 20.

Taking the 40-day period as a whole, there is a clear upward trend in prices. Since it follows on the heels of strong positive returns over the prior 11 months, it is likely to be a manifestation of price momentum. The 1.98 percent cumulative market-adjusted return we observe over these 40 days would then translate into a momentum return of approximately 1 percent per month.<sup>20</sup>

## *II.3. Additional Analyses*

### *II.3.i Adjusting for same-day announcements*

It is not uncommon for multiple earnings announcements to occur on the same date. The *t*-statistics reported in Tables 3 and 4, which assume independence across observations, are therefore likely to be overstated. To ensure that this is not affecting our conclusions, we repeat our analysis, replacing the daily pre- and post-announcement returns of firms announcing on the same date with a single observation whose daily return is equal to the average of those of the individual announcements. This reduces the number of observations used to calculate cumulative pre-announcement (post-announcement) period market-adjusted returns to 1,957 (1,955).

---

<sup>20</sup> Untabulated results reveal an average raw return of 9.4 (15.1) percent over the six-month (12-month) period following the earnings announcements of our past winners. The corresponding returns found by Jegadeesh and Titman (1993) for their top decile of performers are 10.0 and 18.6 percent, respectively.

Table 5, panel A presents the return results; they are qualitatively similar to those previously reported. The average market-adjusted return over the pre-announcement period is now a significant 1.50 percent; in the prior analysis it was 1.58 percent. For the post-announcement period, the average market-adjusted return is a significant -1.77 percent; previously it was -1.86 percent. As before, average daily market-adjusted returns are significant for days -2 through 0 of the pre-announcement period and for all five days of the post-announcement period.

### *II.3.ii. Alternative measures of risk*

To ensure that our findings are not driven by the use of market-adjusted returns as a control for risk, we recompute abnormal returns using the four-factor model of Carhart (1997). We apply this model to calendar-time returns generated by following a two-pronged strategy of (a) purchasing the top percentile of stocks at the close of trading on day -5 and selling them at the close on day 0 and (b) selling the stocks short at the close on day 0 and covering the positions at the end of day 5. We construct long and short portfolios. As of the close of any day's trading the long portfolio is comprised of all stocks for which the current calendar date corresponds to an event day between -5 and -1. Analogously, the short portfolio is comprised of all stocks for which the calendar date corresponds to an event day between 0 and 4.

Assuming an initial investment of one dollar in each stock, the return on each portfolio on calendar date  $d$ ,  $R_d$ , is given by

$$\frac{\sum_{i=1}^{n_d} x_{id} R_{id}}{\sum_{i=1}^{n_d} x_{id}}$$

where  $R_{id}$  is the date  $d$  return on stock  $i$  in the portfolio,  $n_d$  is the number of stocks in the portfolio as of the close of date  $d-1$ , and  $x_{id}$  is the compounded daily return of stock  $i$  from the close of trading on the day it enters the portfolio through day  $d-1$ . (The variable  $x_{id}$  equals 1 for a stock entering on day  $d-1$ .)

The portfolio's average daily abnormal return is given by the intercept,  $\alpha$ , from the following daily time-series regression<sup>21</sup>:

$$R_d - R_{fd} = \alpha + \beta(R_{md} - R_{fd}) + s \cdot SMB_d + h \cdot HML_d + w \cdot WML_d + \varepsilon_d \quad (1)$$

where  $R_{fd}$  is the date  $d$  risk-free rate,  $R_{md}$  is the date  $d$  return on the value-weighted market index,  $SMB_d$  is the date  $d$  return on a value-weighted portfolio of small-cap stocks minus the date  $d$  return on a value-weighted portfolio of large-cap stocks,  $HML_d$  is the date  $d$  return on a value-weighted portfolio of high book-to-market stocks minus the date  $d$  return on a value-weighted portfolio of low book-to-market stocks, and  $WML_d$  is the date  $d$  return on a value-weighted portfolio of stocks with high recent returns minus the date  $d$  return on a value-weighted portfolio of stocks with low recent returns.<sup>22</sup> The regression yields parameter estimates of  $\alpha$ ,  $\beta$ ,  $s$ ,  $h$ , and  $w$ . The error term in the regression is denoted by  $\varepsilon_d$ .

Regression results appear in the first two lines of Table 5, panel B. The average daily abnormal return for the pre-announcement portfolio is a significant 33 basis points. For the post-announcement portfolio it is a significant -28 basis points. Multiplying by five to put these numbers on a comparable footing with the five-day pre- and post-announcement returns previously calculated yields average abnormal returns of 1.65 percent and -1.40 percent,

---

<sup>21</sup> Dates on which the portfolio is empty are not included when estimating the regression.

<sup>22</sup> We thank Ken French and James Davis for providing the daily factor returns.

respectively. These are of the same order of magnitude as our event time market-adjusted returns

### *II.3.iii. Predicting the Earnings Announcement Date*

The extent to which investors are able to capture the pre-announcement period abnormal returns calculated in the previous subsection depends on the precision with which they can forecast firms' earnings announcement dates. Empirical evidence by Bagnoli et al. (2002) suggests that, at least in recent years, many firms have made it easier for investors to do so by disclosing their anticipated announcement dates. Using a database provided by *First Call*, the authors find that over the 1995 – mid-1998 period, almost 26,000 quarterly earnings releases by over 4,400 firms were preceded by the announcement of the anticipated reporting date. The authors further note that the announcing firms in 1995 represent 53 percent of all firms on that year's *First Call* analyst consensus forecast database, and that the proportion increases to 68 percent by 1998. Moreover, in comparing the anticipated and actual earnings release dates, Bagnoli et al. (2002) find them to be identical for approximately 74 percent of their sample. The proportion increases from just under 60 percent in 1995 to over 80 percent in 1998.

These findings, while suggestive of investors being able to exploit the pre-announcement period market-adjusted returns during the latter part of our sample period, are clearly not definitive. Moreover, their ability to do so was undoubtedly much less in earlier years, before the internet brought about an explosion of publicly available financial data.

To estimate the pre-announcement abnormal returns that investors could have captured if no firm disclosed its anticipated release date, we first forecast release dates using the timing of past announcements. Specifically, for each observation in the top percentile we take the

announcement date for the same quarter of the prior year as our estimate of the current quarter's release date. If the prior year's release date is unavailable on *Compustat*, we use the date of the prior quarter's announcement, advanced by three months. In either case, if the predicted date falls on a weekend or holiday, we take the next trading day to be the forecasted release date.

Figure 3 presents the distribution of the number of days difference between actual and forecasted announcement dates. The difference lies between -2 and +2 for almost 38 percent of the sample. For over 55 percent of the sample, the difference is between -5 and +5 days.

We then recompute pre-announcement returns, given a strategy of purchasing each of the stocks in the top percentile at the close of trading 5 days before the *anticipated* announcement date and selling it at the *actual* earnings announcement date. This strategy clearly places a lower bound on the exploitable pre-announcement returns since it does not allow for the possibility that some firms disclose their anticipated announcement dates.

The third line of Table 5, panel B, reports the average daily abnormal return for the pre-announcement period under this revised strategy. It is a significant 0.26 percent. This is equivalent to a five-day average pre-announcement period abnormal return of 1.30 percent. While lower than the return of 1.65 percent that could be earned with foreknowledge of the actual earnings announcement dates, it remains of the same order of magnitude and statistical significance.

#### *II.3.iv. Earnings announcements outside normal trading hours*

In this subsection we compute pre- and post-announcement returns for the subsample of earnings announcements that were made either before or after normal trading hours. By excluding those announcements made during the trading day, we eliminate the noise that arises

from days that are mixtures of pre- and post-announcement trading. By dropping observations for which we do not have an exact announcement time, we eliminate any uncertainty over which days constitute the pre- and post-announcement periods. This ensures that the returns of one period are not inadvertently included in the returns of the other. Of the 2,868 announcements in our sample, 1,462 are known to have been made outside normal trading hours.

Table 5, panel C presents average daily and cumulative pre-announcement and post-announcement market-adjusted returns for this subsample. With the pre-announcement period no longer contaminated by returns from the post-announcement period, the average market-adjusted return for the five days prior to the earnings announcement increases from 1.58 percent to 2.25 percent. Not surprisingly, much of that increase comes on day 0, when the market-adjusted return averages 0.91 percent, as compared to 0.59 percent for our entire sample. For the post-announcement period the average market-adjusted return decreases from -1.86 to -2.2 percent.

We gain further insights by partitioning the day 1 (close-to-close) return into its overnight (close-to-open) and daytime (open-to-close) components. The impetus for doing so stems from Trueman et al. (2003) who find that positive pre-announcement period returns continue through the overnight period of day 1, but turn negative for the remainder of the day. The *Trade and Quotation (TAQ)* database compiled by the National Association of Securities Dealers is our source for opening stock prices. This database contains the prices and trading sizes of intraday stock trades, as well as intraday bid-ask quotes. Since *TAQ* begins in 1993, this analysis is restricted to the 1993-2005 time period. Of the 1,462 after-hours announcements in our subsample, 795 have opening prices on *TAQ*.

As reported in panel D of Table 5, there is a significantly positive day 1 close-to-open average return of 0.93 percent associated with these observations, which is more than offset by a significantly negative open-to-close average return of -1.21 percent.<sup>23</sup> Extending the accumulation of pre-announcement period returns through the open on day 1 therefore increases the average market-adjusted return for this period to 3.09 percent. Commencing the post-announcement period at the open on day 1, rather than at the close on day 0, increases the magnitude of the average market-adjusted return for that period to -3.05 percent. Purchasing our subset of stocks five days before their earnings announcements, closing the positions at the open on day 1, and then initiating short positions which are closed at the end of day 5 would generate an average market-adjusted return over the ten day period of more than 6 percent.

#### *II.3.v. Accounting for transactions costs*

We demonstrate in this subsection that our results are robust to the inclusion of transactions costs, stemming principally from the bid-ask spread and brokerage commissions. To assess the bid-ask spread's impact on pre- and post-announcement period returns, we recompute those returns under the assumption that all share purchases are executed at the prevailing ask price and all share sales occur at the prevailing bid price.<sup>24</sup> More precisely, in calculating pre-announcement returns for our full sample, we assume shares are purchased at the closing ask price on day -5 and sold at the closing bid price on day 0. In computing post-announcement returns, we assume that shares are shorted at the day 0 closing bid price and

---

<sup>23</sup> We report average raw, rather than market-adjusted, returns for these intraday periods because of the lack of data on close-to-open and open-to-close market returns. Given that these periods are very short, raw and market-adjusted returns should be very similar in magnitude.

<sup>24</sup> While we assume that all purchases (sales) are made at the prevailing ask (bid), in reality the dollar amount that can actually be traded at these prices is limited by market depth. The smaller the market depth, the lower will be the dollar returns earned during the pre- and post-announcement periods.

replaced at the closing ask price on day 5. For the subsample of announcements made outside normal trading hours, the pre-announcement position is assumed to be closed at the opening bid price on day 1; the post-announcement short position is established at that price as well.

The TAQ database is our source for opening and closing bid and ask prices. We take as each day's opening bid-ask quote the first one reported on *TAQ* with a time stamp of 9:30 a.m. Eastern time or later. The day's closing bid-ask quote is the last one reported on *TAQ* with a time stamp of no later than 4:00 p.m. Eastern time. Our analysis covers the years 1993 through 2005, the period over which the *TAQ* data is available.

An examination of the data reveals a number of instances where there are large differences between a day's closing (opening) bid or ask and the day's closing (opening) stock price. These deviations likely arise from an erroneous time stamp on an after-hours or before-hours quote, which makes the quote appear to have been in effect during normal trading hours. To ensure that these errors do not affect our results, we drop from our full-sample pre-announcement return calculations any observation for which either (1) the day -5 closing ask is greater than 150 percent of that day's closing stock price or (2) the day 0 closing bid is less than 50 percent of that day's closing stock price. For the post-announcement period return calculations we drop any observation for which either (1) the day 0 closing bid is less than 50 percent of that day's closing stock price or (2) the day 5 closing ask is greater than 150 percent of that day's closing stock price. Similar criteria are applied to eliminate outliers from our subsample of announcements made outside of normal trading hours. As a result of applying these criteria, 49 (45) observations are dropped from our full-sample pre-announcement (post-announcement) period calculations; 51 observations are removed from our after-hours subsample in both the pre- and post-announcement periods.

As presented in Table 5, panel E, cumulative average market-adjusted returns remain significantly different from zero even after accounting for the impact of the bid-ask spread. For our sample as a whole, the 5-day pre-announcement period market-adjusted return averages 0.94; for the 5-day post-announcement period it averages -0.85 percent. For the subsample of announcements made outside of normal trading hours, market-adjusted returns average 1.66 percent for the 5-day pre-announcement period and -1.34 percent post-announcement.<sup>25</sup>

The imposition of brokerage commissions lowers these market-adjusted returns. Our full-sample cumulative average pre- and post-announcement period market-adjusted returns will both remain significant, though, as long as round-trip commissions do not exceed 0.12 percent of transaction value.<sup>26</sup> Assuming a commission of \$10 for each 1,000 shares traded (in line with the commissions charged by discount brokers during the period of our analysis), the round-trip cost of a 1,000 share trade will be less than 0.12 percent as long as the price of the shares traded exceeds \$18.20. The average end-of-quarter share price (untabulated) for the firms in our sample is greater than \$33; consequently, the pre- and post-announcement average market-adjusted returns will retain their significance in the presence of both the bid-ask spread and brokerage commissions. For the subsample of announcements made outside normal trading hours, average market-adjusted returns will remain significant as long as round-trip commissions do not exceed 0.52 percent of transactions value.<sup>27</sup> They fall below 0.52 percent as long as the traded share

---

<sup>25</sup> We also applied this analysis to calendar-time returns, adjusting for risk using the four-factor model. In untabulated results we find that, after accounting for the bid-ask spread, the average daily pre-announcement (post-announcement) abnormal return remains reliably positive (negative).

<sup>26</sup> The imposition of brokerage commissions of  $c$  percent lowers the absolute value of pre-announcement and post-announcement average market-adjusted returns to  $0.94 - c$  and  $0.85 - c$  percent, respectively. With average return standard errors (untabulated) of 0.36 and 0.44 for the pre- and post-announcement periods, respectively, the  $t$ -statistic for the after-commissions average return will exceed 1.65 (which corresponds to a 10 percent significance level) as long as  $c$  does not exceed 0.35 and 0.12, respectively, for the two periods.

<sup>27</sup> The calculation parallels that for the full sample, given subsample average return standard errors of 0.41 and 0.50 (untabulated) for the pre- and post-announcement periods, respectively.

price exceeds \$4. Since all of the stocks in our sample have share prices greater than \$5, the average market-adjusted returns for our after-hours subsample will remain reliably different from zero after the imposition of both the bid-ask spread and brokerage commissions.

### **III. Limited Attention as an Explanation for the Return Pattern Around Earnings Announcements**

In this section we explore the possibility that the anomalous return pattern we document is due, at least in part, to limited attention on the part of small investors. These investors, faced with limited time and resources, are more likely to invest in stocks that draw their attention. Among such stocks are arguably those that have increased sharply in price. Attention is likely to be heightened just before their earnings releases – another attention-grabbing event. Reflective of the presence of small investors in these firms, untabulated results reveal that the average end-of-quarter percentage of shares owned by non-institutional investors is highest (at 70.4 percent) for our past winners. The average over all the other percentiles is 63.1 percent. Also, average end-of-quarter analyst following (at 3.1 analysts), another sign of institutional interest, is lowest for this percentile. The average over the remaining percentiles is 4.2 analysts.

Price pressure from these investors might partially explain the positive pre-announcement returns, while a lessening of that pressure subsequent to the earnings announcements could, in part, explain the post-announcement return reversal. This would be manifested in an abnormally large number of buyer-initiated relative to seller-initiated trades (that is, a positive abnormal order imbalance) for smaller investors during the pre-announcement period (but not necessarily

for larger traders). Once the earnings are released, the smaller investors' positive abnormal order imbalance should disappear.<sup>28</sup>

We employ the Lee-Ready (1991) algorithm to determine whether a trade is buyer-initiated or seller-initiated. A trade is considered to be buyer-initiated (seller-initiated) if it occurs (a) at the asking price (bid price) of the prevailing quote, (b) within the prevailing quote, but closer to the ask than the bid (closer to the bid than the ask), or (c) at the midpoint of the quote and the last price change was positive (negative).<sup>29</sup> The *TAQ* database is our source for intraday prices, quotes, and trading sizes. We include only those trades made during the normal trading hours of 9:30 a.m. to 4:00 p.m. Eastern Time. Lee and Ready (2001) find that quotes are sometimes incorrectly recorded in time ahead of trades and show that trade direction misclassifications can be reduced by comparing the trade price to the quote in effect five seconds earlier. We employ that refinement in our analysis.

We partition the trades reported on *TAQ* into three subgroups: (1) those with a value of \$50,000 or less, which we associate with small traders, (2) those with a value between \$50,000 and \$100,000, which we assume are generated by medium-sized traders, and (3) those with a

---

<sup>28</sup> We also test an alternative, information-based explanation, for our anomalous return results. This explanation requires that unexpectedly positive news comes out during the few days before the earnings announcements of our past winner sample, followed by unexpectedly negative news just afterwards. In untabulated analysis, we proxy for the release of positive pre-announcement news by upward revisions in analysts' pre-announcement earnings forecasts. We proxy for negative post-announcement news by downward revisions in analysts' post-announcement forecasts and/or negative earnings surprises. We find that less than 2 percent of our sample observations are characterized by both an upward revision in analysts' forecasts in the week prior to the earnings announcements and a negative earnings surprise or downward forecast revision during the week thereafter. Not surprisingly, dropping these few observations from our sample does not significantly affect the magnitude of the pre- and post-announcement returns. The same is true if we eliminate all observations having positive pre-announcement analyst forecast revisions (regardless of the sign of the earnings surprise or post-announcement forecast revision, if any) or all observations having negative surprises or post-announcement forecast revisions (regardless of the sign of any pre-announcement revision). These results provide no support for an information-based explanation for the documented return pattern. This is not surprising, given that this potential explanation depends on investors not rationally anticipating that, on average, positive news will be released just before earnings announcements.

<sup>29</sup> Using Nasdaq market data on known trade direction for 313 stocks during the September 1996 – September 1997 period, Ellis et al. (2000) find that the Lee-Ready algorithm correctly classifies 81.05 percent of the trades as buyer- or seller-initiated, the highest percentage among the three different classification schemes they examine.

value of \$100,000 or greater, which we assume come from large traders. In our analyses we include only those announcements for which there are small, medium-sized, and large trades on at least one day of the pre-announcement period as well as on at least one day of the post-announcement period.<sup>30</sup>

Following Lee (1992), the order imbalance for trades of size  $s$ ,  $s$  = small, medium-sized, and large, on event day  $t \in [-4,5]$  for earnings announcement  $n$ ,  $OI_m^s$ , is defined as follows:

$$OI_m^s = \frac{NBUY_m^s - NSELL_m^s}{NTRD_m^s} \quad (2)$$

where  $NBUY_m^s$  ( $NSELL_m^s$ ) denotes the number of buyer-initiated (seller-initiated) trades of size  $s$  during event day  $t$  for observation  $n$ . The difference between  $NBUY_m^s$  and  $NSELL_m^s$  is normalized by the total number of trades of size  $s$  during that day,  $NTRD_m^s$ .

Analogous to the daily order imbalance, we define the order imbalance over days  $t=a$  to  $t=b$  for announcement  $n$ ,  $OI_n^{a,b}$ , as follows:

$$OI_n^{a,b} = \frac{\sum_{t=a}^b NBUY_m - \sum_{t=a}^b NSELL_m}{\sum_{t=a}^b NTRD_m} \quad (3)$$

where the size superscript,  $s$ , is suppressed for notational simplicity. The abnormal order imbalance for the five-day pre-announcement period, denoted by  $AOI_n^{pre}$ , is then given by:

$$AOI_n^{pre} = OI_n^{-4,0} - \frac{1}{12} \sum_{i=0}^{11} OI_n^{30+5i, 34+5i} \quad (4)$$

where the “normal” five-day order imbalance is estimated by averaging the order imbalances of the twelve five-day periods beginning 30 days after the earnings announcement and ending 89

---

<sup>30</sup> This ensures that the same set of announcements make up our small, medium-sized, and large trade subsamples.

days after.<sup>31</sup> Similarly, the abnormal order imbalance for the five-day post-announcement period, denoted by  $AOI_n^{post}$ , is given by:

$$AOI_n^{post} = OI_n^{1,5} - \frac{1}{12} \sum_{i=0}^{11} OI_n^{30+5i, 34+5i} \quad (5)$$

The average abnormal order imbalance for each trader size during the pre- and post-announcement periods is presented in Table 6, panel A. The numbers are consistent with limited attention partially explaining the documented anomalous return pattern around earnings announcements. Small and medium-sized traders, those more likely to exhibit limited attention, have significantly positive average abnormal order imbalances during the pre-announcement period (columns (1) and (2)).<sup>32</sup> In contrast, the average abnormal order imbalance for large traders (column 3), those more likely to be sophisticated, is not reliably different from zero. Once the announcement is made and the attention paid to these stocks ebbs, the significantly positive average order imbalance evidenced by the small and medium-sized traders disappears. They become (marginally) significantly negative. The average abnormal order imbalance for the large traders is also reliably less than zero over the post-announcement period.<sup>33</sup>

---

<sup>31</sup> The “normal” order imbalance is measured using data after the post-announcement period, rather than before, because the earlier period’s order imbalances are biased by our sample selection criteria.

<sup>32</sup> This result means that small and medium-sized investors are increasing their trading during a time when the level of information asymmetry in the marketplace is likely to be heightened. Their behavior contrasts with the documented pattern for overall volume, which, as expected, decreases before earnings announcements (see, for example, Chae (2005)). This implies that either smaller investors are unaware of the magnitude of the adverse selection problem or its impact is outweighed by the attractiveness of the top performing stocks prior to their earnings announcements.

<sup>33</sup> Barber et al. (2008) argue that the introduction of share price decimalization in 2001 and the increased use of computerized trading algorithms has made it more difficult to distinguish between the trades of small and large traders. To determine whether this has had an impact on the nature or significance of our results, we replicate our analysis separately for the 1993-2000 and 2001-2005 periods. In untabulated results, we find for each subperiod that the pre-announcement average abnormal order imbalance is significantly positive for the small and medium-sized traders and insignificantly different from zero for the large traders, just as for our full sample period. During the 1993-2000 subperiod the post-announcement average abnormal order imbalance is significantly negative for the large traders and insignificant for the small and medium-sized ones. None of the three post-announcement average abnormal order imbalances are reliably different from zero over the 2001-2005 subperiod.

Two supplementary tests support the notion of limited attention as a driver of the return pattern around past winners' earnings announcements. In the first test, we regress pre-announcement market-adjusted returns on the abnormal order imbalances of the small, medium-sized, and large traders (as calculated above). If limited attention is at least partially responsible for our results, then the abnormal order imbalance of the small traders should be positively related to the magnitude of these returns. As seen in panel B of Table 6, the coefficient on the small trader abnormal order imbalance is, indeed, positive and significant. In contrast, the coefficients on the medium-sized and large trader abnormal order imbalances are not reliably different from zero.

In the second test, we subdivide our sample period into two subperiods, 1971-1989 and 1990-2005, and calculate average pre-announcement market-adjusted returns for each. During the first subperiod it was arguably more difficult for small investors to access a wide array of media sources and more expensive for them to act on their information (prior to the widespread use of the internet for information gathering and trading) than during the second subperiod. Consequently, we conjecture that if limited attention plays a role in generating the anomalous return pattern we document, then the average pre-announcement market-adjusted return will be smaller during 1971-1989 than during 1990-2005. Our results are consistent with this conjecture. As reported in Table 6, panel C, the average pre-announcement market-adjusted return during the second subperiod is 1.69 percent, which is significantly greater than the corresponding return of 0.74 percent during the first subperiod.<sup>34</sup>

---

<sup>34</sup> The year-by-year returns reported in Figure 1 bear out these differences.

#### **IV. Summary and Conclusions**

In this paper we find a predictable pattern to the returns of past stock market winners around the times of their earnings announcements. For the 1971 – 2005 period, the top percentile of stocks ranked by prior twelve-month price performance experience an economically large and significant average market-adjusted return of 1.58 percent during the five trading days before their earnings announcements and a corresponding return of -1.86 percent in the five days after. The average pre- and post-announcement market-adjusted returns for the subset of stocks that announced earnings outside of normal trading hours are 3.09 and -3.05 percent, respectively. These returns remain significant even after accounting for transactions costs.

We empirically test whether limited attention can, at least in part, explain these anomalous return patterns. Limited attention would suggest that stocks with strong prior returns capture the attention of smaller investors, especially just before their earnings releases, and that the resulting heightened demand for shares pushes up their prices. A lessening of that demand subsequent to the earnings announcements leads to a reversal of returns. Our results support this explanation. In particular, we find that during pre-announcement periods small and medium-sized traders evidence a significantly positive abnormal order imbalance, but large traders do not. After the earnings announcements, the small and medium-sized traders' positive abnormal order imbalances disappear.

This study's findings are reminiscent of the adage "buy on the rumor, sell on the fact." There is a difference here, though, in that the "rumor" is simply that there is an upcoming earnings announcement, not that the news will necessarily be better than expected. In this sense, our results are of a similar nature to those of Bradley et al. (2003). They find that stocks recently taken public rise in price in advance of the ending of the quiet period, with the "rumor" being

only that the lead banker's analyst will shortly be issuing a research report, not that the content of the report will be any more positive than expected.

**Figure 1**

**Average Pre- and Post-Announcement Market-Adjusted Returns, By Year, for Top Percentile of Observations Ranked According to Prior 12-Month Raw Return, 1971 to 2005**

For the firm-quarters in our sample, this figure depicts the average annual pre- and post-announcement market-adjusted returns, by year, for the top percentile of observations ranked according to prior 12-month raw return. Prior 12-month raw return is the raw stock return for the 12-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date. The market-adjusted return for the post-announcement period equals the sum of the daily market-adjusted returns for the five trading days after the earnings announcement date.

**Figure 2**

**Cumulative Average Pre- and Post-Announcement Market-Adjusted Returns for Top Percentile of Observations  
Ranked According to Prior 11-Month Raw Return**

For the firm-quarters in our sample, this figure depicts the cumulative average market-adjusted return on each day from day -19 to day +20 around earnings announcements for the top percentile of observations ranked according to prior 11-month raw return. Prior 11-month raw return is the raw stock return for the 11-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The cumulative market-adjusted return equals the sum of the market-adjusted returns from day -19 through the current day. Day 0 is the earnings announcement day.

**Figure 3**  
**Histogram of the Difference (in days) Between the Actual and Predicted Earnings Announcement Dates**

This figure depicts the distribution of the number of days between the actual and predicted earnings announcement dates for the observations in the top percentile. For each observation the predicted announcement date is equal to the actual announcement date for the same quarter of the prior year. If the prior year's release date is unavailable on Compustat, the date of the prior quarter's announcement, advanced by three months, is used. If the predicted date falls on a weekend or holiday, the next trading day is taken to be the forecasted release date.

**Table 1**  
**Descriptive Statistics by Decile of Prior 12-Month Raw Return**

For the firm-quarters in our sample, this table reports statistics on end-of-quarter market capitalization (panel A), prior 12-month raw return (panel B), pre-announcement market-adjusted return (panel C), and post-announcement market-adjusted return (panel D), by decile of prior 12-month raw return. Prior 12-month raw return is the raw stock return for the 12-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date. The market-adjusted return for the post-announcement period equals the sum of the daily market-adjusted returns for the five trading days after the earnings announcement date.  $t$ -statistics for the pre- and post-announcement average market-adjusted returns are also presented.

**Panel A: Market value (in millions)**

Decile of prior 12-month raw return	Number of observations	Mean	Median
1 (lowest)	29,349	775	130
2	29,362	1,515	186
3	29,381	1,802	237
4	29,354	2,067	273

**Table 2**  
**Descriptive Statistics for the Top Ten Percentiles of Observations Ranked**  
**According to Prior 12-Month Raw Return**

For the firm-quarters in our sample, this table reports statistics on end-of-quarter market capitalization (panel A), prior 12-month raw return (panel B), pre-announcement market-adjusted return (panel C), and post-announcement market-adjusted return (panel D), for the top ten percentiles of observations ranked according to prior 12-month raw return. Prior 12-month raw return is the raw stock return for the 12-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date. The market-adjusted return for the post-announcement period equals the sum of the daily market-adjusted returns for the five trading days after the earnings announcement date. *t*-statistics for the pre- and post-announcement average market-adjusted returns are also presented.

**Panel A: Market value (in millions)**

Percentile of prior 12-month raw return	Number of observations	Mean	Median
91	2,936	1,872	256
92	2,939	1,421	229
93	2,940	1,624	231
94	2,935	1,433	230
95	2,939	1,270	232
96	2,936	1,261	212
97	2,938	984	204
98	2,941	987	202
99	2,930	844	177
100 (highest)	2,912	726	168

**Panel B: Prior 12-month raw return (in percent)**

Percentile of prior 12-month raw return	Number of observations	Mean
91	2,936	81.8
92	2,939	87.6
93	2,940	94.6
94	2,935	103.2
95	2,939	113.5
96	2,936	126.6
97	2,938	144.1
98	2,941	170.4
99	2,930	216.6
100 (highest)	2,912	399.0

**Panel C: Pre-announcement market-adjusted return (in percent)**

Percentile of prior 12-month raw return	Number of observations	Mean	t-stat
91	2,930	0.41	2.93
92	2,929	0.61	4.02
93	2,936	0.5	3.39
94	2,935	0.84	5.64
95	2,932	0.63	4.14
96	2,934	0.81	5.43
97	2,934	1.03	6.21
98	2,933	0.95	5.29
99	2,926	1.15	6.53
100 (highest)	2,906	1.36	7.11

**Panel D: Post-announcement market-adjusted return (in percent)**

Percentile of prior 12-month raw return	Number of observations	Mean	t-stat
91	2,932	-0.33	-2.40
92	2,929	-0.39	-2.75
93	2,934	-0.5	-3.43
94	2,928	-0.26	-1.80
95	2,931	-0.38	-2.49
96	2,927	-0.74	-4.74
97	2,930	-0.75	-4.65
98	2,928	-0.86	-5.06
99	2,923	-1.13	-6.28
100 (highest)	2,900	-1.75	-9.03

**Table 3****Average Daily Market-Adjusted Return for the Top Percentile of Observations Ranked According to Prior 12-Month Raw Return**

For the 2,868 firm-quarters in our sample, this table reports the average daily market-adjusted return (in percent) around earnings announcements for the top percentile of observations ranked according to prior 12-month raw return. (The results reflect the use of the refined earnings announcement dates.) Prior 12-month raw return is the raw stock return for the 12-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date (day -4 to day 0). The market-adjusted return for the post-announcement period equals the sum of the daily market-adjusted returns for the five trading days after the earnings announcement date (day +1 to day +5). *t*-statistics appear below each day's average market-adjusted return.

Trading day relative to earnings announcement day	Average daily market-adjusted return
-4	0.04
	0.52
-3	0.11
	1.29
-2	0.29
	3.14
-1	0.53
	5.83
0	0.59
	5.27
+1	-0.31
	-2.21
+2	-0.51
	-5.85
+3	-0.44
	-5.47
+4	-0.37
	-4.59
+5	-0.24
	-3.02
Pre-announcement period (days -4 to 0)	1.58
	8.36
Post-announcement period (days +1 to +5)	-1.86
	-8.66

**Table 4**

**Average Daily and Cumulative Average Market-Adjusted Returns from Day -19 to Day +20  
Around Earnings Announcements for the Top Percentile of Observations Ranked  
According to Prior 11-Month Raw Return**

For the firm-quarters in our sample, this table reports the average daily and cumulative average market-adjusted returns (in percent) from day -19 to day +20 around earnings announcements for the top percentile of observations ranked according to prior 11-month raw return. (Since the top percentile changes somewhat when the shorter prior return period is used, the average daily market-adjusted returns for days -4 through 5 differ somewhat from those reported in Table 3.) Day 0 is the earnings announcement day. Prior 11-month raw return is the raw stock return for the 11-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The cumulative market-adjusted return on any day is the sum of the daily market-adjusted returns through that day.

Trading day relative to earnings announcement day	Average daily market- adjusted return	<i>t</i> -statistic	Cumulative average market-adjusted return
-19	0.04	0.49	0.04
-18	0.12	1.45	0.16
-17	0.05	0.61	0.21
-16	0.18	1.96	0.39
-15	0.12	1.41	0.51
-14	0.09	1.03	0.60
-13	0.30	3.32	0.90

+19	0.12	1.48	1.88
+20	0.10	1.35	1.98

**Table 5**  
**Robustness Tests of Pre-Announcement and Post-Announcement Returns for the Top**  
**Percentile of Observations Ranked According to Prior 12-Month Raw Return**

For the firm-quarters in our sample, panel A reports the average daily pre- and post-announcement market-adjusted returns (in percent) for the top percentile of observations ranked according to prior 12-month raw return, after replacing the event-window returns of firms announcing on the same date by a single observation with daily returns equal to the average of those of the individual announcements. Prior 12-month raw return is the raw stock return for the 12-month period ending on the last trading day of the just-ended quarter. The daily market-adjusted return equals the raw return minus the market return for that day. The market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date (day -4 to day 0). The market-adjusted return for the post-announcement period equals the sum of the daily market-adjusted returns for the five trading days after the earnings announcement date (day +1 to day +5). Panel B reports intercepts from two calendar-time four-factor model regressions (referred to as “pre-announcement” and “post-announcement”) whose dependent variables are the return on a portfolio comprised at each day’s close of all stocks for which the current calendar date corresponds to an event day between -5 and -1 minus the risk free rate, and the return on a portfolio comprised at each day’s close of all stocks for which the current calendar date corresponds to an event day between 0 and +5 minus the risk free rate, respectively. We also report the intercept from a pre-announcement regression which is comprised at each day’s close of all stocks for which the current calendar date corresponds to an event day between -5 *relative to the predicted, rather than the actual, announcement date* and day -1. For each observation the predicted announcement date is equal to the actual announcement date for the same quarter of the prior year. If the prior year’s release date is unavailable on Compustat, the date of the prior quarter’s announcement, advanced by three months, is used. If the predicted date falls on a weekend or holiday, the next trading day is taken to be the forecasted release date. The independent variables for the regressions are (a) the day’s return on the value-weighted market index minus the risk-free rate, (b) the day’s return on a value-weighted portfolio of small-cap stocks minus the return on a value-weighted portfolio of large-cap stocks, (c) the day’s return on a value-weighted portfolio of high book-to-market stocks minus the return on a value-weighted portfolio of low book-to-market stocks, and (d) the day’s return on a value-weighted portfolio of stocks with high recent returns minus the return on a value-weighted portfolio of stocks with low recent returns. Panel C reports average daily market-adjusted returns (in percent) for a sample that includes only those earnings announcements made outside of normal trading hours. Panel D reports average daily market-adjusted returns (in percent) for a sample that includes only those earnings announcements made outside of normal trading hours for which day +1 opening prices are available on the Trade and Quotation (TAQ) database. For this panel, the market-adjusted return for the pre-announcement period equals the sum of the daily market-adjusted returns for the five trading days up to and including the earnings announcement date (day -4 to day 0) plus the close-to-open raw return on day +1 (close on day 0 to open on day +1). The market-adjusted return for the post-announcement period equals the sum of the day +1 open-to-close raw return and the market-adjusted returns for days +2 through +5. Panel E presents cumulative average market-adjusted returns for the pre- and post-announcement periods, for both the full sample and the subsample of after-hours announcements, taking the bid-ask spread into account. These returns are calculated assuming that all share purchases are executed at the prevailing ask price and all share sales are executed at the prevailing bid price.

**Panel A: Controlling for same-day earnings announcements**

Trading day relative to earnings announcement day	Number of observations	Mean	t-statistic
-4	1,961	0.06	0.68
-3	1,960	0.10	1.07
-2	1,960	0.35	3.61
-1	1,958	0.45	4.68
0	1,960	0.51	4.29
Pre-announcement period (days -4 to 0)	1,957	1.50	7.33
+1	1,960	-0.35	-2.63
+2	1,960	-0.48	-5.26
+3	1,959	-0.35	-4.00
+4	1,958	-0.35	-4.07
+5	1,955	-0.24	-2.56
Post-announcement period (days +1 to +5)	1,955	-1.77	-7.81

**Panel B: Intercepts from four-factor model regressions**

Portfolio	Regression intercept	t-statistic
Pre-announcement (using actual earnings release dates)	0.33	5.71
Post-announcement	-0.28	-5.45
Pre-announcement (using predicted earnings release dates)	0.26	5.02

**Table 5 - Continued**

**Panel C: Average market-adjusted returns for the subsample of earnings announcements made outside of normal trading hours**

Trading day relative to earnings announcement day	Number of observations	Mean	t-statistic
-4	1,462	0.19	1.41
-3	1,462	0.13	1.06
-2	1,462	0.37	2.57
-1	1,461	0.64	4.63
0	1,462	0.91	6.35
Pre-announcement period (days -4 to 0)	1,461	2.25	8.29
+1	1,462	-0.30	-1.28
+2	1,462	-0.63	-4.77
+3	1,460	-0.52	-4.26
+4	1,461	-0.46	-3.73
+5	1,461	-0.29	-2.48
Post-announcement period (days +1 to +5)	1,460	-2.20	-6.35

**Panel D: Average market-adjusted returns for the subsample of earnings announcements made outside of normal trading hours and where opening prices are available on TAQ**

Portfolio	Number of observations	Mean	t-statistic
-4	795	0.21	1.19
-3	795	-0.04	-0.23
-2	795	0.40	1.99
-1	795	0.71	3.62
0	795	0.89	4.61
Close day 0 to open day 1	795	0.93	4.25
Pre-announcement period (day -4 through day 1 open)	795	3.09	7.11
Open-to-close day 1	795	-1.21	-4.79
+2	795	-0.61	-3.41
+3	795	-0.48	-2.62
+4	795	-0.66	-3.86
+5	795	-0.11	-0.69
Post-announcement period (open on day +1 through day +5)	795	-3.05	-6.99

**Panel E: Average market-adjusted returns after accounting for the impact of the bid-ask spread**

	Number of observations	Mean	t-statistic
Overall sample:			
Pre-announcement period (days -4 to 0)	943	0.94	2.60
Post-announcement period (days +1 to +5)	945	-0.85	-1.91
Subsample of earnings announcements made outside of normal trading hours:			
Pre-announcement period (day -4 through day 1 open)	759	1.66	4.09
Post-announcement period (day 1 open through day +5)	756	-1.34	-2.67

**Table 6**  
**Tests for Limited Attention**

Panel A of this table reports the average abnormal order imbalance during the pre-announcement period and during the post-announcement period for small trades (less than \$50,000 in value), medium-sized trades (between \$50,000 and \$100,000), and large trades (greater than \$100,000). For each trade size and each period, the order imbalance is calculated as the difference between the total number of buyer-initiated trades of that size minus the total number of seller-initiated trades of that size over the period, scaled by the total number of those size trades. The abnormal order imbalance equals the order imbalance less the average order imbalance over days +30 to +89. Day 0 is the earnings announcement day. *t*-statistics appear below each abnormal order imbalance. Panel B presents the coefficient estimates (and corresponding *t*-statistics) for a regression of the pre-announcement market-adjusted return (equal to the sum of the raw minus market returns for the five trading days up to and including the earnings announcement date) on the average abnormal order imbalance during the pre-announcement period for small trades (less than \$50,000 in value), medium-sized trades (between \$50,000 and \$100,000), and large trades (greater than \$100,000). Panel C reports the average pre-announcement market-adjusted return for the 1971-89 and 1990-2005 subperiods.

**Panel A: Pre- and Post-Announcement Period Average Abnormal Order Imbalances, by Trade Size**

Period	Number of observations	Average abnormal order imbalance for		
		small trades	medium-sized trades	large trades
Pre-announcement period (days -4 to 0)	570	0.0145 2.74	0.0287 3.29	0.0039 0.39
Post-announcement period (days +1 to +5)	570	-0.0088 -1.71	-0.0130 -1.65	-0.0183 -1.93

**Panel B: Regression of pre-announcement market-adjusted return (days -4 to 0) on small, medium-sized, and large trade abnormal order imbalances**

	Number of observations	pre-announcement abnormal order imbalance for:		
		small trades	medium-sized trades	large trades
Coefficient estimate	570	0.285	0.012	0.022
<i>t</i> -statistic		7.47	0.51	1.10

**Panel C: Average pre-announcement market-adjusted return (days -4 to 0): 1971-89 vs. 1990-2005**

	1971-89	1990-2005	<i>t</i> -statistic of return difference
Average pre-announcement market-adjusted return	0.74%	1.69%	2.59
Number of observations	1007	1899
